1. Introduction

This document is a guide for developers wishing to create distributed applications that take advantage of ZooKeeper's coordination services. It contains conceptual and practical information.

The first four sections of this guide present higher level discussions of various ZooKeeper concepts. These are necessary both for an understanding of how ZooKeeper works as well how to work with it. It does not contain source code, but it does assume a familiarity with the problems associated with distributed computing. The sections in this first group are:

- [The ZooKeeper Data Model](#)
- [ZooKeeper Sessions](#)
- [ZooKeeper Watches](#)
- [Consistency Guarantees](#)

The next four sections provide practical programming information. These are:

- [Building Blocks: A Guide to ZooKeeper Operations](#)
- [Bindings](#)
- [Program Structure, with Simple Example](#) *[tbd]*
- [Gotchas: Common Problems and Troubleshooting](#)

The book concludes with an [appendix](#) containing links to other useful, ZooKeeper-related information.

Most of information in this document is written to be accessible as stand-alone reference material. However, before starting your first ZooKeeper application, you should probably at least read the chapters on the [ZooKeeper Data Model](#) and [ZooKeeper Basic Operations](#). Also, the [Simple Programming Example](#) *[tbd]* is helpful for understanding the basic structure of a ZooKeeper client application.

2. The ZooKeeper Data Model

ZooKeeper has a hierarchal name space, much like a distributed file system. The only difference is that each node in the namespace can have data associated with it as well as children. It is like having a file system that allows a file to also be a directory. Paths to nodes are always expressed as canonical, absolute, slash-separated paths; there are no relative reference. Any unicode character can be used in a path subject to the following constraints:

- The null character (`\u0000`) cannot be part of a path name. (This causes problems with the

C binding.)

- The following characters can't be used because they don't display well, or render in confusing ways: `\u0001` - `\u0019` and `\u007F` - `\u009F`.
- The following characters are not allowed: `\ud800` - `\uF8FFF`, `\uFFFF0` - `\uFFFFF`, `\uXFFFE` - `\uXFFFF` (where X is a digit 1 - E), `\uF0000` - `\uFFFFF`.
- The "." character can be used as part of another name, but "." and ".." cannot alone be used to indicate a node along a path, because ZooKeeper doesn't use relative paths. The following would be invalid: `"/a/b/./c"` or `"/a/b/../c"`.
- The token "zookeeper" is reserved.

2.1. ZNodes

Every node in a ZooKeeper tree is referred to as a *znode*. Znodes maintain a stat structure that includes version numbers for data changes, acl changes. The stat structure also has timestamps. The version number, together with the timestamp allow ZooKeeper to validate the cache and to coordinate updates. Each time a znode's data changes, the version number increases. For instance, whenever a client retrieves data, it also receives the version of the data. And when a client performs an update or a delete, it must supply the version of the data of the znode it is changing. If the version it supplies doesn't match the actual version of the data, the update will fail. (This behavior can be overridden. For more information see...)
[tbd...]

Note:

In distributed application engineering, the word *node* can refer to a generic host machine, a server, a member of an ensemble, a client process, etc. In the ZooKeeper documentatin, *znodes* refer to the data nodes. *Servers* to refer to machines that make up the ZooKeeper service; *quorum peers* refer to the servers that make up an ensemble; client refers to any host or process which uses a ZooKeeper service.

Znodes are the main entity that a programmer access. They have several characteristics that are worth mentioning here.

2.1.1. Watches

Clients can set watches on znodes. Changes to that znode trigger the watch and then clear the watch. When a watch triggers, ZooKeeper sends the client a notification. More information about watches can be found in the section [ZooKeeper Watches](#).

2.1.2. Data Access

The data stored at each znode in a namespace is read and written atomically. Reads get all the data bytes associated with a znode and a write replaces all the data. Each node has an Access Control List (ACL) that restricts who can do what.

2.1.3. Ephemeral Nodes

ZooKeeper also has the notion of ephemeral nodes. These znodes exist as long as the session that created the znode is active. When the session ends the znode is deleted. Because of this behavior ephemeral znodes are not allowed to have children.

2.1.4. Sequence Nodes -- Unique Naming

When creating a znode you can also request that ZooKeeper append a monotonically increasing counter to the end of path. This counter is unique to the parent znode. The counter has a format of %010d -- that is 10 digits with 0 (zero) padding (the counter is formatted in this way to simplify sorting), i.e. "<path>0000000001". See [Queue Recipe](#) for an example use of this feature. Note: the counter used to store the next sequence number is a signed int (4bytes) maintained by the parent node, the counter will overflow when incremented beyond 2147483647 (resulting in a name "<path>-2147483647").

2.2. Time in ZooKeeper

ZooKeeper tracks time multiple ways:

- **Zxid**

Every change to the ZooKeeper state receives a stamp in the form of a *zxid* (ZooKeeper Transaction Id). This exposes the total ordering of all changes to ZooKeeper. Each change will have a unique zxid and if zxid1 is smaller than zxid2 then zxid1 happened before zxid2.

- **Version numbers**

Every change to a node will cause an increase to one of the version numbers of that node. The three version numbers are version (number of changes to the data of a znode), cversion (number of changes to the children of a znode), and aversion (number of changes to the ACL of a znode).

- **Ticks**

When using multi-server ZooKeeper, servers use ticks to define timing of events such as status uploads, session timeouts, connection timeouts between peers, etc. The tick time is only indirectly exposed through the minimum session timeout (2 times the tick time); if a client requests a session timeout less than the minimum session timeout, the server will

tell the client that the session timeout is actually the minimum session timeout.

- **Real time**

ZooKeeper doesn't use real time, or clock time, at all except to put timestamps into the stat structure on znode creation and znode modification.

2.3. ZooKeeper Stat Structure

The Stat structure for each znode in ZooKeeper is made up of the following fields:

- **czxid**

The zxid of the change that caused this znode to be created.

- **mzxid**

The zxid of the change that last modified this znode.

- **ctime**

The time in milliseconds from epoch when this znode was created.

- **mtime**

The time in milliseconds from epoch when this znode was last modified.

- **version**

The number of changes to the data of this znode.

- **cversion**

The number of changes to the children of this znode.

- **aversion**

The number of changes to the ACL of this znode.

- **ephemeralOwner**

The session id of the owner of this znode if the znode is an ephemeral node. If it is not an ephemeral node, it will be zero.

- **dataLength**

The length of the data field of this znode.

- **numChildren**

The number of children of this znode.

3. ZooKeeper Sessions

To create a client session the application code must provide a connection string containing a comma separated list of host:port pairs, each corresponding to a ZooKeeper server (e.g. "127.0.0.1:4545" or "127.0.0.1:3000,127.0.0.1:3001,127.0.0.1:3002"). The ZooKeeper client library will pick an arbitrary server and try to connect to it. If this connection fails, or if the client becomes disconnected from the server for any reason, the client will automatically try the next server in the list, until a connection is (re-)established.

Added in 3.2.0: An optional "chroot" suffix may also be appended to the connection string. This will run the client commands while interpreting all paths relative to this root (similar to the unix chroot command). If used the example would look like: "127.0.0.1:4545/app/a" or "127.0.0.1:3000,127.0.0.1:3001,127.0.0.1:3002/app/a" where the client would be rooted at "/app/a" and all paths would be relative to this root - ie getting/setting/etc... "/foo/bar" would result in operations being run on "/app/a/foo/bar" (from the server perspective). This feature is particularly useful in multi-tenant environments where each user of a particular ZooKeeper service could be rooted differently. This makes re-use much simpler as each user can code his/her application as if it were rooted at "/", while actual location (say /app/a) could be determined at deployment time.

When a client gets a handle to the ZooKeeper service, ZooKeeper creates a ZooKeeper session, represented as a 64-bit number, that it assigns to the client. If the client connects to a different ZooKeeper server, it will send the session id as a part of the connection handshake. As a security measure, the server creates a password for the session id that any ZooKeeper server can validate. The password is sent to the client with the session id when the client establishes the session. The client sends this password with the session id whenever it reestablishes the session with a new server.

One of the parameters to the ZooKeeper client library call to create a ZooKeeper session is the session timeout in milliseconds. The client sends a requested timeout, the server responds with the timeout that it can give the client. The current implementation requires that the timeout be a minimum of 2 times the tickTime (as set in the server configuration) and a maximum of 20 times the tickTime.

Another parameter to the ZooKeeper session establishment call is the default watcher. Watchers are notified when any state change occurs in the client. For example if the client loses connectivity to the server the client will be notified, or if the client's session expires, etc... This watcher should consider the initial state to be disconnected (i.e. before any state changes events are sent to the watcher by the client lib). In the case of a new connection, the first event sent to the watcher is typically the session connection event.

The session is kept alive by requests sent by the client. If the session is idle for a period of time that would timeout the session, the client will send a PING request to keep the session alive. This PING request not only allows the ZooKeeper server to know that the client is still active, but it also allows the client to verify that its connection to the ZooKeeper server is still active. The timing of the PING is conservative enough to ensure reasonable time to detect a dead connection and reconnect to a new server.

Once a connection to the server is successfully established (connected) there are basically two cases where the client lib generates connectionloss (the result code in c binding, exception in Java -- see the API documentation for binding specific details) when either a synchronous or asynchronous operation is performed and one of the following holds:

1. The application calls an operation on a session that is no longer alive/valid
2. The ZooKeeper client disconnects from a server when there are pending operations to that server, i.e., there is a pending asynchronous call.

4. ZooKeeper Watches

All of the read operations in ZooKeeper - **getData()**, **getChildren()**, and **exists()** - have the option of setting a watch as a side effect. Here is ZooKeeper's definition of a watch: a watch event is one-time trigger, sent to the client that set the watch, which occurs when the data for which the watch was set changes. There are three key points to consider in this definition of a watch:

- **One-time trigger**

One watch event will be sent to the client the data has changed. For example, if a client does a `getData("/znode1", true)` and later the data for `/znode1` is changed or deleted, the client will get a watch event for `/znode1`. If `/znode1` changes again, no watch event will be sent unless the client has done another read that sets a new watch.

- **Sent to the client**

This implies that an event is on the way to the client, but may not reach the client before the successful return code to the change operation reaches the client that initiated the change. Watches are sent asynchronously to watchers. ZooKeeper provides an ordering guarantee: a client will never see a change for which it has set a watch until it first sees the watch event. Network delays or other factors may cause different clients to see watches and return codes from updates at different times. The key point is that everything seen by the different clients will have a consistent order.

- **The data for which the watch was set**

This refers to the different ways a node can change. It helps to think of ZooKeeper as

maintaining two lists of watches: data watches and child watches. `getData()` and `exists()` set data watches. `getChildren()` sets child watches. Alternatively, it may help to think of watches being set according to the kind of data returned. `getData()` and `exists()` return information about the data of the node, whereas `getChildren()` returns a list of children. Thus, `setData()` will trigger data watches for the znode being set (assuming the set is successful). A successful `create()` will trigger a data watch for the znode being created and a child watch for the parent znode. A successful `delete()` will trigger both a data watch and a child watch (since there can be no more children) for a znode being deleted as well as a child watch for the parent znode.

Watches are maintained locally at the ZooKeeper server to which the client is connected. This allows watches to be light weight to set, maintain, and dispatch. When a client connects to a new server, the watch will be triggered for any session events. Watches will not be received while disconnected from a server. When a client reconnects, any previously registered watches will be reregistered and triggered if needed. In general this all occurs transparently. There is one case where a watch may be missed: a watch for the existence of a znode not yet created will be missed if the znode is created and deleted while disconnected.

4.1. What ZooKeeper Guarantees about Watches

With regard to watches, ZooKeeper maintains these guarantees:

- Watches are ordered with respect to other events, other watches, and asynchronous replies. The ZooKeeper client libraries ensures that everything is dispatched in order.
- A client will see a watch event for a znode it is watching before seeing the new data that corresponds to that znode.
- The order of watch events from ZooKeeper corresponds to the order of the updates as seen by the ZooKeeper service.

4.2. Things to Remember about Watches

- Watches are one time triggers; if you get a watch event and you want to get notified of future changes, you must set another watch.
- Because watches are one time triggers and there is latency between getting the event and sending a new request to get a watch you cannot reliably see every change that happens to a node in ZooKeeper. Be prepared to handle the case where the znode changes multiple times between getting the event and setting the watch again. (You may not care, but at least realize it may happen.)

- A watch object, or function/context pair, will only be triggered once for a given notification. For example, if the same watch object is registered for an exists and a `getData` call for the same file and that file is then deleted, the watch object would only be invoked once with the deletion notification for the file.
- When you disconnect from a server (for example, when the server fails), you will not get any watches until the connection is reestablished. For this reason session events are sent to all outstanding watch handlers. Use session events to go into a safe mode: you will not be receiving events while disconnected, so your process should act conservatively in that mode.

5. ZooKeeper access control using ACLs

ZooKeeper uses ACLs to control access to its znodes (the data nodes of a ZooKeeper data tree). The ACL implementation is quite similar to UNIX file access permissions: it employs permission bits to allow/disallow various operations against a node and the scope to which the bits apply. Unlike standard UNIX permissions, a ZooKeeper node is not limited by the three standard scopes for user (owner of the file), group, and world (other). ZooKeeper does not have a notion of an owner of a znode. Instead, an ACL specifies sets of ids and permissions that are associated with those ids.

Note also that an ACL pertains only to a specific znode. In particular it does not apply to children. For example, if `/app` is only readable by `ip:172.16.16.1` and `/app/status` is world readable, anyone will be able to read `/app/status`; ACLs are not recursive.

ZooKeeper supports pluggable authentication schemes. Ids are specified using the form *scheme:id*, where *scheme* is the authentication scheme that the id corresponds to. For example, `ip:172.16.16.1` is an id for a host with the address `172.16.16.1`.

When a client connects to ZooKeeper and authenticates itself, ZooKeeper associates all the ids that correspond to a client with the client's connection. These ids are checked against the ACLs of znodes when a client tries to access a node. ACLs are made up of pairs of (*scheme:expression*, *perms*). The format of the *expression* is specific to the scheme. For example, the pair (`ip:19.22.0.0/16`, `READ`) gives the `READ` permission to any clients with an IP address that starts with `19.22`.

5.1. ACL Permissions

ZooKeeper supports the following permissions:

- **CREATE**: you can create a child node

- **READ**: you can get data from a node and list its children.
- **WRITE**: you can set data for a node
- **DELETE**: you can delete a child node
- **ADMIN**: you can set permissions

The *CREATE* and *DELETE* permissions have been broken out of the *WRITE* permission for finer grained access controls. The cases for *CREATE* and *DELETE* are the following:

You want A to be able to do a set on a ZooKeeper node, but not be able to *CREATE* or *DELETE* children.

CREATE without *DELETE*: clients create requests by creating ZooKeeper nodes in a parent directory. You want all clients to be able to add, but only request processor can delete. (This is kind of like the APPEND permission for files.)

Also, the *ADMIN* permission is there since ZooKeeper doesn't have a notion of file owner. In some sense the *ADMIN* permission designates the entity as the owner. ZooKeeper doesn't support the LOOKUP permission (execute permission bit on directories to allow you to LOOKUP even though you can't list the directory). Everyone implicitly has LOOKUP permission. This allows you to stat a node, but nothing more. (The problem is, if you want to call `zoo_exists()` on a node that doesn't exist, there is no permission to check.)

5.1.1. Builtin ACL Schemes

ZooKeeper has the following built in schemes:

- **world** has a single id, *anyone*, that represents anyone.
- **auth** doesn't use any id, represents any authenticated user.
- **digest** uses a *username:password* string to generate MD5 hash which is then used as an ACL ID identity. Authentication is done by sending the *username:password* in clear text. When used in the ACL the expression will be the *username:base64 encoded SHA1 password digest*.
- **ip** uses the client host IP as an ACL ID identity. The ACL expression is of the form *addr/bits* where the most significant *bits* of *addr* are matched against the most significant *bits* of the client host IP.

5.1.2. ZooKeeper C client API

The following constants are provided by the ZooKeeper C library:

- `const int ZOO_PERM_READ;` //can read node's value and list its children

- `const int ZOO_PERM_WRITE;` // can set the node's value
- `const int ZOO_PERM_CREATE;` // can create children
- `const int ZOO_PERM_DELETE;` // can delete children
- `const int ZOO_PERM_ADMIN;` // can execute `set_acl()`
- `const int ZOO_PERM_ALL;` // all of the above flags OR'd together

The following are the standard ACL IDs:

- `struct Id ZOO_ANYONE_ID_UNSAFE;` // ('world', 'anyone')
- `struct Id ZOO_AUTH_IDS;` // ('auth', '')

ZOO_AUTH_IDS empty identity string should be interpreted as “the identity of the creator”.

ZooKeeper client comes with three standard ACLs:

- `struct ACL_vector ZOO_OPEN_ACL_UNSAFE;`
// (ZOO_PERM_ALL, ZOO_ANYONE_ID_UNSAFE)
- `struct ACL_vector ZOO_READ_ACL_UNSAFE;` // (ZOO_PERM_READ,
ZOO_ANYONE_ID_UNSAFE)
- `struct ACL_vector ZOO_CREATOR_ALL_ACL;`
// (ZOO_PERM_ALL, ZOO_AUTH_IDS)

The ZOO_OPEN_ACL_UNSAFE is completely open free for all ACL: any application can execute any operation on the node and can create, list and delete its children. The ZOO_READ_ACL_UNSAFE is read-only access for any application. CREATE_ALL_ACL grants all permissions to the creator of the node. The creator must have been authenticated by the server (for example, using “*digest*” scheme) before it can create nodes with this ACL.

The following ZooKeeper operations deal with ACLs:

- `int zoo_add_auth (zhandle_t *zh, const char* scheme, const char* cert, int certLen, void_completion_t completion, const void *data);`

The application uses the `zoo_add_auth` function to authenticate itself to the server. The function can be called multiple times if the application wants to authenticate using different schemes and/or identities.

- `int zoo_create (zhandle_t *zh, const char *path, const char *value, int valuelen, const struct ACL_vector *acl, int flags, char *realpath, int max_realpath_len);`

`zoo_create(...)` operation creates a new node. The `acl` parameter is a list of ACLs associated

with the node. The parent node must have the CREATE permission bit set.

- `int zoo_get_acl (zhandle_t *zh, const char *path, struct ACL_vector *acl, struct Stat *stat);`

This operation returns a node's ACL info.

- `int zoo_set_acl (zhandle_t *zh, const char *path, int version, const struct ACL_vector *acl);`

This function replaces node's ACL list with a new one. The node must have the ADMIN permission set.

Here is a sample code that makes use of the above APIs to authenticate itself using the “foo” scheme and create an ephemeral node “/xyz” with create-only permissions.

Note:

This is a very simple example which is intended to show how to interact with ZooKeeper ACLs specifically. See `.../trunk/src/c/src/cli.c` for an example of a proper C client implementation

```
#include <string.h>
#include <errno.h>

#include "zookeeper.h"

static zhandle_t *zh;

/**
 * In this example this method gets the cert for your
 * environment -- you must provide
 */
char *foo_get_cert_once(char* id) { return 0; }

/** Watcher function -- empty for this example, not something you should
 * do in real code */
void watcher(zhandle_t *zh, int type, int state, const char *path,
             void *watcherCtx) {}

int main(int argc, char argv) {
    char buffer[512];
    char p[2048];
    char *cert=0;
    char appId[64];

    strcpy(appId, "example.foo_test");
    cert = foo_get_cert_once(appId);
    if(cert!=0) {
        fprintf(stderr,
```

```

        "Certificate for appid [%s] is [%s]\n", appId, cert);
    strncpy(p, cert, sizeof(p)-1);
    free(cert);
} else {
    fprintf(stderr, "Certificate for appid [%s] not found\n", appId);
    strcpy(p, "dummy");
}

zoo_set_debug_level(ZOO_LOG_LEVEL_DEBUG);

zh = zookeeper_init("localhost:3181", watcher, 10000, 0, 0, 0);
if (!zh) {
    return errno;
}
if (zoo_add_auth(zh, "foo", p, strlen(p), 0, 0) != ZOK)
    return 2;

struct ACL_CREATE_ONLY_ACL[] = {{ZOO_PERM_CREATE, ZOO_AUTH_IDS}};
struct ACL_vector CREATE_ONLY = {1, CREATE_ONLY_ACL};
int rc = zoo_create(zh, "/xyz", "value", 5, &CREATE_ONLY, ZOO_EPHEMERAL,
    buffer, sizeof(buffer)-1);

/** this operation will fail with a ZNOAUTH error */
int buflen= sizeof(buffer);
struct Stat stat;
rc = zoo_get(zh, "/xyz", 0, buffer, &buflen, &stat);
if (rc) {
    fprintf(stderr, "Error %d for %s\n", rc, __LINE__);
}

zookeeper_close(zh);
return 0;
}

```

6. Pluggable ZooKeeper authentication

ZooKeeper runs in a variety of different environments with various different authentication schemes, so it has a completely pluggable authentication framework. Even the builtin authentication schemes use the pluggable authentication framework.

To understand how the authentication framework works, first you must understand the two main authentication operations. The framework first must authenticate the client. This is usually done as soon as the client connects to a server and consists of validating information sent from or gathered about a client and associating it with the connection. The second operation handled by the framework is finding the entries in an ACL that correspond to client. ACL entries are *<idspec, permissions>* pairs. The *idspec* may be a simple string match against the authentication information associated with the connection or it may be a expression that is evaluated against that information. It is up to the implementation of the authentication plugin to do the match. Here is the interface that an authentication plugin must

implement:

```
public interface AuthenticationProvider {
    String getScheme();
    KeeperException.Code handleAuthentication(ServerCnxn cnxn, byte
authData[]);
    boolean isValid(String id);
    boolean matches(String id, String aclExpr);
    boolean isAuthenticated();
}
```

The first method *getScheme* returns the string that identifies the plugin. Because we support multiple methods of authentication, an authentication credential or an *idspec* will always be prefixed with *scheme:*. The ZooKeeper server uses the scheme returned by the authentication plugin to determine which ids the scheme applies to.

handleAuthentication is called when a client sends authentication information to be associated with a connection. The client specifies the scheme to which the information corresponds. The ZooKeeper server passes the information to the authentication plugin whose *getScheme* matches the scheme passed by the client. The implementor of *handleAuthentication* will usually return an error if it determines that the information is bad, or it will associate information with the connection using *cnxn.getAuthInfo().add(new Id(getScheme(), data))*.

The authentication plugin is involved in both setting and using ACLs. When an ACL is set for a znode, the ZooKeeper server will pass the id part of the entry to the *isValid(String id)* method. It is up to the plugin to verify that the id has a correct form. For example, *ip:172.16.0.0/16* is a valid id, but *ip:host.com* is not. If the new ACL includes an "auth" entry, *isAuthenticated* is used to see if the authentication information for this scheme that is associated with the connection should be added to the ACL. Some schemes should not be included in auth. For example, the IP address of the client is not considered as an id that should be added to the ACL if auth is specified.

ZooKeeper invokes *matches(String id, String aclExpr)* when checking an ACL. It needs to match authentication information of the client against the relevant ACL entries. To find the entries which apply to the client, the ZooKeeper server will find the scheme of each entry and if there is authentication information from that client for that scheme, *matches(String id, String aclExpr)* will be called with *id* set to the authentication information that was previously added to the connection by *handleAuthentication* and *aclExpr* set to the id of the ACL entry. The authentication plugin uses its own logic and matching scheme to determine if *id* is included in *aclExpr*.

There are two built in authentication plugins: *ip* and *digest*. Additional plugins can adding using system properties. At startup the ZooKeeper server will look for system properties that

start with "zookeeper.authProvider." and interpret the value of those properties as the class name of an authentication plugin. These properties can be set using the `-Dzookeeper.authProvider.X=com.f.MyAuth` or adding entries such as the following in the server configuration file:

```
authProvider.1=com.f.MyAuth
authProvider.2=com.f.MyAuth2
```

Care should be taking to ensure that the suffix on the property is unique. If there are duplicates such as `-Dzookeeper.authProvider.X=com.f.MyAuth` and `-Dzookeeper.authProvider.X=com.f.MyAuth2`, only one will be used. Also all servers must have the same plugins defined, otherwise clients using the authentication schemes provided by the plugins will have problems connecting to some servers.

7. Consistency Guarantees

ZooKeeper is a high performance, scalable service. Both reads and write operations are designed to be fast, though reads are faster than writes. The reason for this is that in the case of reads, ZooKeeper can serve older data, which in turn is due to ZooKeeper's consistency guarantees:

Sequential Consistency

Updates from a client will be applied in the order that they were sent.

Atomicity

Updates either succeed or fail -- there are no partial results.

Single System Image

A client will see the same view of the service regardless of the server that it connects to.

Reliability

Once an update has been applied, it will persist from that time forward until a client overwrites the update. This guarantee has two corollaries:

1. If a client gets a successful return code, the update will have been applied. On some failures (communication errors, timeouts, etc) the client will not know if the update has applied or not. We take steps to minimize the failures, but the only guarantee is only present with successful return codes. (This is called the *monotonicity condition* in Paxos.)
2. Any updates that are seen by the client, through a read request or successful update, will never be rolled back when recovering from server failures.

Timeliness

The clients view of the system is guaranteed to be up-to-date within a certain time bound. (On the order of tens of seconds.) Either system changes will be seen by a client within this bound, or the client will detect a service outage.

Using these consistency guarantees it is easy to build higher level functions such as leader election, barriers, queues, and read/write revocable locks solely at the ZooKeeper client (no additions needed to ZooKeeper). See [Recipes and Solutions](#) for more details.

Note:

Sometimes developers mistakenly assume one other guarantee that ZooKeeper does *not* in fact make. This is:

Simultaneously Consistent Cross-Client Views

ZooKeeper does not guarantee that at every instance in time, two different clients will have identical views of ZooKeeper data. Due to factors like network delays, one client may perform an update before another client gets notified of the change. Consider the scenario of two clients, A and B. If client A sets the value of a znode /a from 0 to 1, then tells client B to read /a, client B may read the old value of 0, depending on which server it is connected to. If it is important that Client A and Client B read the same value, Client B should call the **sync()** method from the ZooKeeper API method before it performs its read.

So, ZooKeeper by itself doesn't guarantee that changes occur synchronously across all servers, but ZooKeeper primitives can be used to construct higher level functions that provide useful client synchronization. (For more information, see the [ZooKeeper Recipes](#). [tbd:...]).

8. Bindings

The ZooKeeper client libraries come in two languages: Java and C. The following sections describe these.

8.1. Java Binding

There are two packages that make up the ZooKeeper Java binding: **org.apache.zookeeper** and **org.apache.zookeeper.data**. The rest of the packages that make up ZooKeeper are used internally or are part of the server implementation. The **org.apache.zookeeper.data** package is made up of generated classes that are used simply as containers.

The main class used by a ZooKeeper Java client is the **ZooKeeper** class. Its two constructors differ only by an optional session id and password. ZooKeeper supports session recovery accross instances of a process. A Java program may save its session id and password to stable storage, restart, and recover the session that was used by the earlier instance of the program.

When a ZooKeeper object is created, two threads are created as well: an IO thread and an event thread. All IO happens on the IO thread (using Java NIO). All event callbacks happen on the event thread. Session maintenance such as reconnecting to ZooKeeper servers and maintaining heartbeat is done on the IO thread. Responses for synchronous methods are also

processed in the IO thread. All responses to asynchronous methods and watch events are processed on the event thread. There are a few things to notice that result from this design:

- All completions for asynchronous calls and watcher callbacks will be made in order, one at a time. The caller can do any processing they wish, but no other callbacks will be processed during that time.
- Callbacks do not block the processing of the IO thread or the processing of the synchronous calls.
- Synchronous calls may not return in the correct order. For example, assume a client does the following processing: issues an asynchronous read of node `/a` with `watch` set to true, and then in the completion callback of the read it does a synchronous read of `/a`. (Maybe not good practice, but not illegal either, and it makes for a simple example.)

Note that if there is a change to `/a` between the asynchronous read and the synchronous read, the client library will receive the watch event saying `/a` changed before the response for the synchronous read, but because the completion callback is blocking the event queue, the synchronous read will return with the new value of `/a` before the watch event is processed.

Finally, the rules associated with shutdown are straightforward: once a ZooKeeper object is closed or receives a fatal event (`SESSION_EXPIRED` and `AUTH_FAILED`), the ZooKeeper object becomes invalid. On a close, the two threads shut down and any further access on zookeeper handle is undefined behavior and should be avoided.

8.2. C Binding

The C binding has a single-threaded and multi-threaded library. The multi-threaded library is easiest to use and is most similar to the Java API. This library will create an IO thread and an event dispatch thread for handling connection maintenance and callbacks. The single-threaded library allows ZooKeeper to be used in event driven applications by exposing the event loop used in the multi-threaded library.

The package includes two shared libraries: `zookeeper_st` and `zookeeper_mt`. The former only provides the asynchronous APIs and callbacks for integrating into the application's event loop. The only reason this library exists is to support the platforms where a `pthread` library is not available or is unstable (i.e. FreeBSD 4.x). In all other cases, application developers should link with `zookeeper_mt`, as it includes support for both Sync and Async API.

8.2.1. Installation

If you're building the client from a check-out from the Apache repository, follow the steps

outlined below. If you're building from a project source package downloaded from apache, skip to step 3.

1. Run `ant compile_jute` from the ZooKeeper top level directory (`.../trunk`). This will create a directory named "generated" under `.../trunk/src/c`.
2. Change directory to the `.../trunk/src/c` and run `autoreconf -if` to bootstrap **autoconf**, **automake** and **libtool**. Make sure you have **autoconf version 2.59** or greater installed. Skip to step 4.
3. If you are building from a project source package, unzip/untar the source tarball and `cd` to the `zookeeper-x.x.x/src/c` directory.
4. Run `./configure <your-options>` to generate the makefile. Here are some of options the **configure** utility supports that can be useful in this step:
 - `--enable-debug`
Enables optimization and enables debug info compiler options. (Disabled by default.)
 - `--without-syncapi`
Disables Sync API support; `zookeeper_mt` library won't be built. (Enabled by default.)
 - `--disable-static`
Do not build static libraries. (Enabled by default.)
 - `--disable-shared`
Do not build shared libraries. (Enabled by default.)

Note:

See `INSTALL` for general information about running **configure**.

5. Run `make` or `make install` to build the libraries and install them.
6. To generate doxygen documentation for the ZooKeeper API, run `make doxygen-doc`. All documentation will be placed in a new subfolder named `docs`. By default, this command only generates HTML. For information on other document formats, run `./configure --help`

8.2.2. Using the C Client

You can test your client by running a ZooKeeper server (see instructions on the project wiki page on how to run it) and connecting to it using one of the cli applications that were built as

part of the installation procedure. `cli_mt` (multithreaded, built against `zookeeper_mt` library) is shown in this example, but you could also use `cli_st` (singlethreaded, built against `zookeeper_st` library):

```
$ cli_mt zookeeper_host:9876
```

This is a client application that gives you a shell for executing simple ZooKeeper commands. Once successfully started and connected to the server it displays a shell prompt. You can now enter ZooKeeper commands. For example, to create a node:

```
> create /my_new_node
```

To verify that the node's been created:

```
> ls /
```

You should see a list of node who are children of the root node `"/`.

In order to be able to use the ZooKeeper API in your application you have to remember to

1. Include ZooKeeper header: `#include <zookeeper/zookeeper.h`
2. If you are building a multithreaded client, compile with `-DTHREADED` compiler flag to enable the multi-threaded version of the library, and then link against against the `zookeeper_mt` library. If you are building a single-threaded client, do not compile with `-DTHREADED`, and be sure to link against the `zookeeper_st` library.

Refer to [Program Structure, with Simple Example](#) for examples of usage in Java and C. *[tbd]*

9. Building Blocks: A Guide to ZooKeeper Operations

This section surveys all the operations a developer can perform against a ZooKeeper server. It is lower level information than the earlier concepts chapters in this manual, but higher level than the ZooKeeper API Reference. It covers these topics:

- [Connecting to ZooKeeper](#)

9.1. Handling Errors

Both the Java and C client bindings may report errors. The Java client binding does so by throwing `KeeperException`, calling `code()` on the exception will return the specific error code. The C client binding returns an error code as defined in the enum `ZOO_ERRORS`. API callbacks indicate result code for both language bindings. See the API documentation (javadoc for Java, doxygen for C) for full details on the possible errors and their meaning.

9.2. Connecting to ZooKeeper

9.3. Read Operations

9.4. Write Operations

9.5. Handling Watches

9.6. Miscellaneous ZooKeeper Operations

11. Gotchas: Common Problems and Troubleshooting

So now you know ZooKeeper. It's fast, simple, your application works, but wait ... something's wrong. Here are some pitfalls that ZooKeeper users fall into:

1. If you are using watches, you must look for the connected watch event. When a ZooKeeper client disconnects from a server, you will not receive notification of changes until reconnected. If you are watching for a znode to come into existence, you will miss the event if the znode is created and deleted while you are disconnected.
2. You must test ZooKeeper server failures. The ZooKeeper service can survive failures as long as a majority of servers are active. The question to ask is: can your application handle it? In the real world a client's connection to ZooKeeper can break. (ZooKeeper server failures and network partitions are common reasons for connection loss.) The ZooKeeper client library takes care of recovering your connection and letting you know what happened, but you must make sure that you recover your state and any outstanding requests that failed. Find out if you got it right in the test lab, not in production - test with a ZooKeeper service made up of a several of servers and subject them to reboots.
3. The list of ZooKeeper servers used by the client must match the list of ZooKeeper servers that each ZooKeeper server has. Things can work, although not optimally, if the client list is a subset of the real list of ZooKeeper servers, but not if the client lists ZooKeeper servers not in the ZooKeeper cluster.

4. Be careful where you put that transaction log. The most performance-critical part of ZooKeeper is the transaction log. ZooKeeper must sync transactions to media before it returns a response. A dedicated transaction log device is key to consistent good performance. Putting the log on a busy device will adversely effect performance. If you only have one storage device, put trace files on NFS and increase the snapshotCount; it doesn't eliminate the problem, but it can mitigate it.
5. Set your Java max heap size correctly. It is very important to *avoid swapping*. Going to disk unnecessarily will almost certainly degrade your performance unacceptably. Remember, in ZooKeeper, everything is ordered, so if one request hits the disk, all other queued requests hit the disk.

To avoid swapping, try to set the heapsize to the amount of physical memory you have, minus the amount needed by the OS and cache. The best way to determine an optimal heap size for your configurations is to *run load tests*. If for some reason you can't, be conservative in your estimates and choose a number well below the limit that would cause your machine to swap. For example, on a 4G machine, a 3G heap is a conservative estimate to start with.

Outside the formal documentation, there're several other sources of information for ZooKeeper developers.
